Starting Values for SUCCOTASH

David Gerard 2016-06-28

Abstract

I run SUCCOTASH from different intial values of Z and λ . Likelihood ratios are always below $1 + \epsilon$. Estimates of λ and π_0 are very similar between the two starting position strategies.

Simulation Setup

I ran through 100 repetitions of generating data from GTEX muscle data under the following parameter conditions:

- $n \in \{10, 20, 40\},\$
- p = 1000.
- $\pi_0 \in \{0.5, 0.9, 1\},\$
- The alternative distribution being just a standard normal. New alternatives are generated every iteration.

I extracted the most expressed p genes from the GTEX muscle data and n samples are chosen at random. Half of these samples are randomly given the "treatment" label 1, the other half given the "control" label 0. Of the p genes, $\pi_0 p$ were chosen to be non-null. Signal was added by a Poisson-thinning approach, where the log-2 fold change was sampled from one of five the alternative models above. That is

$$A_1, \dots, A_{p/2} \sim f$$
 (1)
 $B_i = 2^{A_i} \text{ for } i = 1, \dots, p/2,$

$$B_i = 2^{A_i} \text{ for } i = 1, \dots, p/2,$$
 (2)

where f is from the table above. If $A_i > 0$ then we replace $Y_{[1:(n/2),i]}$ with $Binom(Y_{[j,i]},1/B_i)$ for $j=1,\dots,n$ $1, \ldots, n/2$. If $A_i < 0$ then we replace $Y_{[(n/2+1):n,i]}$ with $Binom(Y_{[j,i]}, B_i)$ for $j = n/2 + 1, \ldots, n$.

I now describe the justification for this. Suppose that

$$Y_{ij} \sim Poisson(\lambda_i).$$
 (3)

Let x_i be the indicator of treatment vs control for individual i. Let Ω be the set of non-null genes. Let Z be the new dataset derived via the steps above. That is

$$Z_{ij}|Y_{ij} = \begin{cases} Binom(Y_{ij}, 2^{A_j x_i}) & \text{if } A_j < 0 \text{ and } j \in \Omega \\ Binom(Y_{ij}, 2^{-A_j(1-x_i)}) & \text{if } A_j > 0 \text{ and } j \in \Omega \\ Y_{ij} & \text{if } j \notin \Omega. \end{cases}$$

$$(4)$$

Then

$$Z_{ij}|A_j, A_j < 0, j \in \Omega \sim Poisson(2^{A_j x_i} \lambda_j)$$
(5)

$$Z_{ij}|A_j, A_j > 0, j \in \Omega \sim Poisson(2^{-A_j(1-x_i)}\lambda_j), \tag{6}$$

and

$$E[\log_2(Z_{ij}) - \log_2(Z_{kj})|A_j, A_j < 0, j \in \Omega] \approx A_j x_i - A_j x_k, \text{ and}$$

$$(7)$$

$$E[\log_2(Z_{ij}) - \log_2(Z_{kj})|A_j, A_j > 0, j \in \Omega] \approx -A_j(1 - x_i) + A_j(1 - x_k). \tag{8}$$

if individual i is in the treatment group and individual k is in the control group, then this just equals A_j . I treat the A_j 's as the true coefficient values when calculating the MSE below.

Methods

I ran two versions of SUCCOTASH that differ only in their initial values for Z (the confounders) and λ (the variance inflation parameter). The two versions are:

- Z and λ start at their MLE's assuming that the unimodal distribution is a pointmass at 0.
- Each element of Z is a standard normal draw and λ is a χ_1^2 draw.

Both versions use a normal likelihood and a mixture of normals.

I kept their estimates of π_0 , their AUC's, their MSE's, their estimates of the variance inflation parameter, their maximized log-likelihood, and their maximized null log-likelihood (maximized over Z and λ but not over the space of unimodal densities).

Results

Read in simulation results.

```
library(ggplot2)
library(reshape2)
library(dplyr)

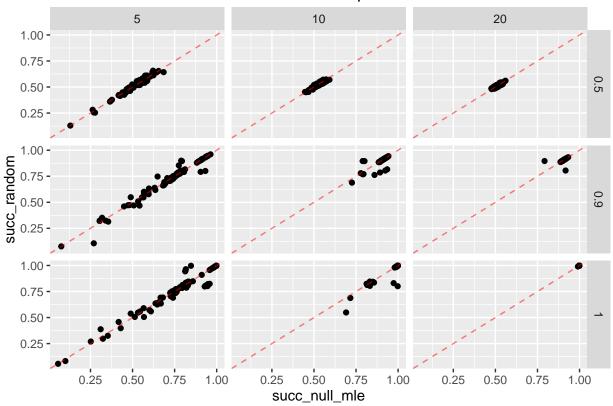

pi0_mat <- read.csv(file = "pi0_ruvash_alpha1.csv")
mse_mat <- read.csv(file = "mse_ruvash_alpha1.csv")
auc_mat <- read.csv(file = "auc_ruvash_alpha1.csv")
scale_val_mat <- read.csv(file = "scale_val_ruvash_alpha1.csv")
llike_mat <- read.csv(file = "llike_ruvash_alpha1.csv")
null_llike_mat <- read.csv(file = "null_llike_ruvash_alpha1.csv")</pre>
```

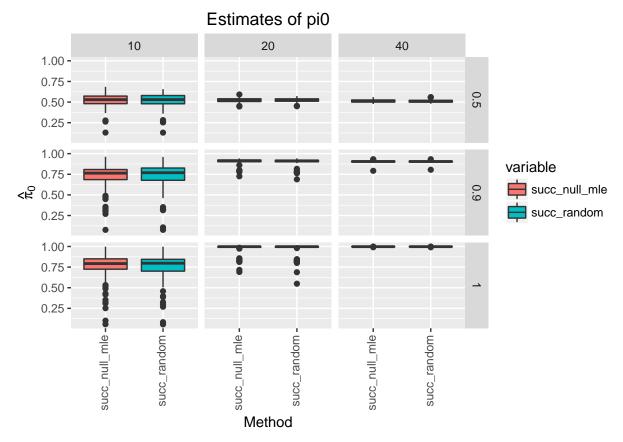

Estimates of π_0 and λ are about the same

Estimates of π_0 are pretty good and are usually about the same for both methods.

```
ggplot(data = pi0_mat, mapping = aes(x = succ_null_mle, y = succ_random)) +
    geom_point() +
    facet_grid(nullpi ~ Nsamp) +
    geom_abline(intercept = 0, slope = 1, col = 2, lty = 2, alpha = 1/2) +
    ggtitle("Estimates of pi0")
```

Estimates of pi0

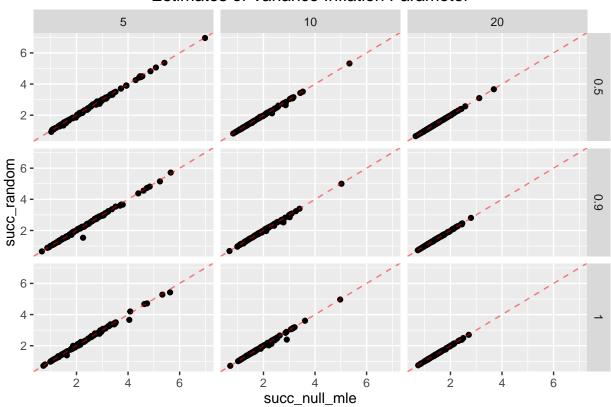

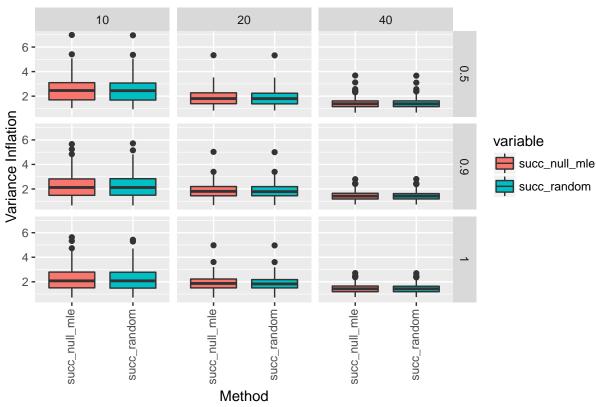

Estimates of the scaling parameter are almost always exactly the same

```
ggplot(data = scale_val_mat, mapping = aes(x = succ_null_mle, y = succ_random)) +
    geom_point() +
    facet_grid(nullpi ~ Nsamp) +
    geom_abline(intercept = 0, slope = 1, col = 2, lty = 2, alpha = 1/2) +
    ggtitle("Estimates of Variance Inflation Parameter")
```

Estimates of Variance Inflation Parameter

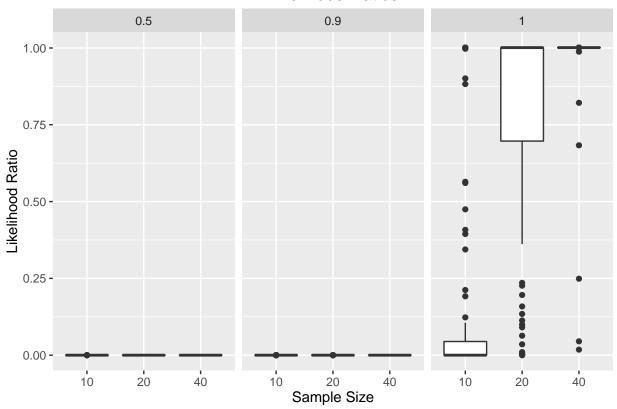

Likelihood Ratios

Now I'll just look at starting at the null-MLEs and compare the maximized log-likelihood vs the null maximized log-likelihood. All of the likelihood ratios are less than 1.

Likelihood Ratios

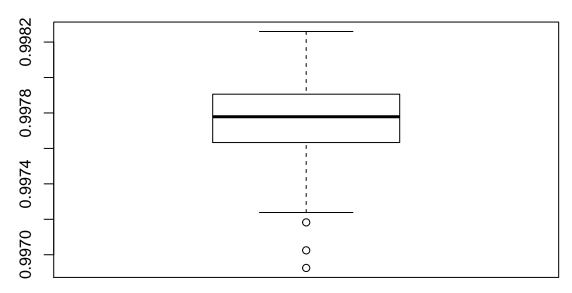

Well, the max log-likelihood ratio is actually 0.0017, but the estimate of π_0 in this scenario is 0.998. In general, the estimates of π_0 for all scenarios that have a log-likelihood ratio greater than 0 is

```
pi0_mat$succ_null_mle[llike_nml$logLR > 0]
```

```

## [141] 0.9975 0.9979 0.9976 0.9979 0.9981 0.9976 0.9977 0.9978 0.9978 0.9976
## [151] 0.9975 0.9978 0.9974 0.9979 0.9978 0.9976 0.9976 0.9978 0.9977 0.9978
## [161] 0.9976 0.9978 0.9977 0.9978 0.9976 0.9977
```

```
boxplot(pi0_mat$succ_null_mle[llike_nml$logLR > 0])
```

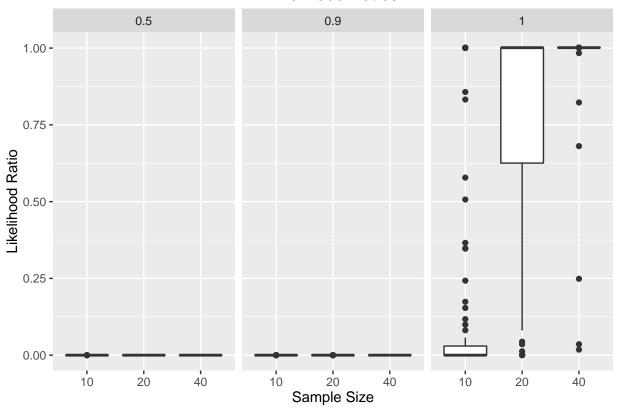

So I think the optimization algorithm leaves the all-null setting then reaches some tolerance threshold before returning to the all-null setting.

Same as above but using random starting locations

Now I'll just look at starting at random locations and compare the maximized log-likelihood vs the null maximized log-likelihood. All of the likelihood ratios are less than 1.

Likelihood Ratios

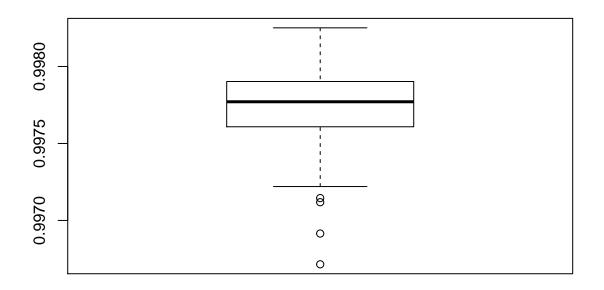

Well, the max log-likelihood ratio is actually 0.002, but the estimate of π_0 in this scenario is 0.9979. In general, the estimates of π_0 for all scenarios that have a log-likelihood ratio greater than 0 is

pi0_mat\$succ_random[llike_ran\$logLR > 0]

```
